## Abstract

The burning of agricultural field residue, such as stalks and stubble, during the wheat and rice harvesting seasons in the Indo-Gangetic plains results in substantial emissions of trace gases and particles. This pollution can have adverse health and climate impacts. Our paper uses a representative sample of farmers from the seven districts of Punjab to identify the determinants of emissions from open-field burning of rice residue. The study finds that the use of coarse varieties of rice as opposed to fine-grained varieties such as Basmati increases the likelihood of farmers using the combine-harvester technology, which in turn makes burning almost certain. Although a ban on burning residue was in effect in Amritsar district during the year of the survey, it had moderate impact on burning. We used a second sample of users of the Happy Seeder machine in order to examine the potential for adoption of this new technology. This machine plants seed into loose residue, making burning of residue unnecessary. A comparison of the Happy Seeder with conventional practice shows that the new technology does not increase the cost of field preparation. We also found no evidence of an increase or decrease in the mean yield of wheat from using the Happy Seeder. We conclude that farmers will be slow to adopt the Happy Seeder since it has no strong advantage or disadvantage from the view point of private profits. Thus, the state would need to play a more significant role in promoting this machine in order to reduce residue burning and associated costs that are mostly external to the farmer.

**Key Words:** Rice Residue Burning, Emissions, Stalks and stubble, Happy Seeder Technology, Punjab.

# Causes of Emissions from Agricultural Residue Burning in North-West India: Evaluation of a Technology Policy Response

## 1. Introduction

An important source of atmospheric pollution in the Indo-Gangetic plains is biomass burning (of agricultural field residue such as stalks and stubble) during wheat and rice harvesting periods (Venkataraman et al., 2006). This has adverse impacts not only on the health of the population (Long et al., 1998) but also on the regional climate and crop output (Auffhammer et al., 2006). In the present study, we therefore look for answers to the following questions: what factors explain the open-field burning of rice residue in Punjab, India and what are the available alternatives to this practice? Understanding why farmers resort to burning is essential for policy makers to arrive at suitable mitigation policies which would reduce rice- residue burning in the region.

The 'rice-wheat cropping system' (RWCS) is the dominant cropping system in South Asia (Hobbs and Morris, 1996). This system involves growing rice and wheat in rotation throughout the year where rice and wheat is either grown in the same plot in the same year or in different plots in the same year or in the same plot in different years. Uttar Pradesh, Punjab, Haryana, Bihar, Madhya Pradesh, and Himachal Pradesh have the largest areas under this system among the Indian states.

Koopmans and Koppejan (1997) estimated that India generated approximately 507.8 million tons of on-field crop residue during 1997, of which 43% was rice and 23% wheat. According to estimates from Streets et al. (2003), farmers burnt 16% of this crop residue. The results from Venkataraman et al. (2006) suggest that farmers in India burnt 116 million metric tons of crop residue in 2001, albeit with a strong regional variation. Their estimates suggest that, in all, open burning of crop residue accounted for about 25% of black carbon, organic matter, and carbon monoxide emissions, 9-13 % of fine particulate matter (PM<sub>2.5</sub>) and carbon dioxide emissions and about 1% of sulphur dioxide emissions. Moreover, the authors found that a majority of the fires that occurred in the western Indo-Gangetic plain during the months of May and October corresponded with, the two major harvesting seasons for rice and wheat. Field burning in the major agricultural states of Punjab, Haryana and western Uttar Pradesh was the largest potential contributor to these emissions.

Gustafsson et al. (2009) employed radiocarbon analysis as an atmospheric tracer to measure biomass and fossil-fuel contributions to the South Asian atmospheric brown cloud. The technique they employed found the contribution of biomass combustion to black carbon emissions (at 46% for elemental carbon and at 68% for soot carbon) to be much larger than that detected by other tracer techniques. Thus, they proposed that- '*both biomass combustion (such as residential cooking and agricultural burning) and fossil fuel combustion should be targeted to mitigate climate effects and improve air quality.*'

Black carbon emissions are the second largest contributors to current global warming, after carbon dioxide emissions (Ramanathan and Carmichael, 2008). Long et al. (1998), who studied the health consequences from burning of agricultural residue, through a survey of 428 participants with underlying respiratory disorders and exposure to pollution from the burning of agricultural residue, found that people with underlying respiratory disorders were susceptible to the air pollution caused by burning of agricultural residue. Their study found that the pollution either aggravated underlying symptoms or induced additional air-pollution-related symptoms. Auffhammer et al. (2006) found that joint reductions in brown clouds and green-house gases had complementary, positive impacts on rice harvests in India over the period 1972-1998. Brown cloud attributed harvest reductions alone are estimated to have grown from 3.94% during the 1966-84 period to 10.6% during the 1985-1998 period. Biomass regulation, therefore, becomes both a national and international priority. In this paper we will determine the impacts of both open-fields burning of agricultural residue and of alternative technologies that eliminate the need for biomass burning.

This is the first study that uses farm-level data in order to explore the possibility of regulating emissions from open field burning of rice residue in Punjab. We conducted two surveys for the purpose of generating the data. The first survey collected information on the method of residue disposal and its determinants for the purpose of identifying the factors that explain open-field burning of rice residue. We find that the use of coarse (as opposed to Basmati) varieties of rice increases the likelihood of farmers harvesting rice using the combine-harvester, which in turn scatters residue and therefore makes the burning of biomass almost certain.

We use the second survey to examine a technology called the Happy Seeder machine, which precludes the burning of rice residue. We conclude that this technology has the potential to reduce emissions from residue burning in Punjab. Happy Seeder is a tractor-mounted machine that cuts and lifts the rice straw, sows wheat into the bare soil, and deposits the straw over the sown area as mulch.<sup>1</sup> Farmers can therefore sow wheat immediately after the rice harvest, precluding the need for burning rice residue.

We find that the use of the Happy Seeder does not increase the cost of field preparation for wheat that follows the rice harvest compared to conventional practice, which usually involves burning residue. This finding is based on comparisons of different plots of the same farmers, with and without the Happy Seeder technology. This result implies that, on its own, the Happy Seeder technology will spread only slowly since it has no strong advantage or disadvantage from the point of view of the private profitability of the farmer. Accordingly, there is a strong case for promoting the machine through extension and possibly subsidies in order to reduce residue burning, the costs of which are mostly external to the farmer. These are important results given that rice residue is the biggest contributor to emissions from open-field burning of crop residue in this region (Badarinath et al., 2006).

The open-field burning of crop residue generated from mechanized harvesting of cereal crops is not a problem peculiar to India. Yang et al. (2008) estimated the emissions from crop residue burning in the Suqian region of the Jiangsu Province of China. In Suqian, farmers practice the rice-wheat cropping system widely. According to the authors, farmers burnt about 82% of the wheat straw and 32% of the rice straw in the field during the period 2001-2005. They attribute the open-field burning of cereal residues to the practice of mechanized harvesting of cereal crops by a combine-harvester.

However, in the case of China, unlike Punjab, farmers burn more wheat than rice residue. One reason why farmers in China are busiest in the month of June is that wheat is harvested in June; whereas farmers in Punjab find themselves more hard-pressed during the months of October to December. Another reason is the universal preference for wheat residue as livestock feed by Punjabi farmers. Thus, in Punjab farmers collect wheat residues and trade the surplus. Farooq et al. (2007) also associate agricultural residue burning with the use of the combine-harvester to harvest crops in the Punjab province of Pakistan. There is also widespread use of wheat residue as animal feed in this region. Thus, the authors report intensive collection of wheat residue and large-scale burning of rice residue. These findings support our contention that the Happy Seeder technology can reduce rice-residue burning beyond the Indian Punjab.

The rest of the paper is organized as follows. In the next section we describe the sampling design. In Section 3, we discuss the factors that explain the rice residue burning in Punjab. Section 4 details the factors which explain field burning of rice residue in Punjab while in section 5 we analyze the profitability of the Happy Seeder technology. Section 6 concludes with policy implications.

## **2. Study Area and Sampling**

The empirical analysis uses two samples, one, a representative sample of farmers and the other a sample of users of the Happy Seeder machine. We collected the two samples from the state of Punjab<sup>2</sup> because the Happy Seeder technology is so far only available in this state. Moreover, with rice and wheat yields of 3858 kg per hectare and 4179 kg per hectare respectively in 2005-06, the state occupied the top position in the country in terms of food

<sup>1</sup> A protective cover placed over the soil to retain moisture, reduce erosion, provide nutrients, and suppress weed growth and seed germination.

<sup>2</sup> In 2006-2007, Punjab was the fourth largest producer of rice and the second largest producer of wheat in India, producing 11% of the country's rice output and 19% of its wheat output (Ram, 2008)

grain yield (Ram, 2008). The ratio of net irrigated area to net area sown stood at 0.95 in 2005-06 and is the highest in the country (Ram, 2008) because the Happy Seeder technology is so far only available in this state.

We selected the representative samples of farmers from the districts of Amritsar, Ludhiana and Sangrur. We chose these three districts because we wanted to capture geographical variation across Punjab. In the second stage, we selected ten villages for sampling from each of the three districts using the probability proportional to size technique. This technique ensured that farmers in the larger villages had the same probability of getting into the sample as farmers in the smaller villages and vice-versa. We obtained the list of villages from the 2001 Census of India. The voter list constituted the sampling frame within a village because a voter list assigns a unique house-hold number to each household in a village and specifies the names of all household members who are at least eighteen years of age at the time of preparation of the list.<sup>3</sup> The data collected includes information on costs incurred by farmers in preparing the field for the wheat crop by conventional tillage.

We surveyed ten households within each village. Since there would be people who did not engage in any farming activity in each village, we randomly selected forty households from each voter list. If the first household among the forty house-holds was a farm household, we included it in the survey. If that was not the case, we dropped it and contacted the second household. We followed this procedure until the enumerator was able to complete nine interviews. In order to find out if farmers with large landholdings behaved differently from farmers with small landholdings, we included one farmer with a large landholding from each village in the sample. We did this by asking the respondents to provide the names of the five largest landowners in their village. We randomly selected one farmer from this list for the interview.

For the purposes of the study, we defined a farm household as a group of individuals, related by blood or marriage, living on the same premises that share a kitchen and practice the rice-wheat cropping system. The respondents to the questionnaire were men who were actively involved in day-to-day farming activity.

We collected data at plot level since a farm may not be one consolidated unit. The total farm area for most farmers is distributed across plots and farmers follow different practices on different plots. We arrived at the size of a farm unit by summing up farm land owned and the farm land leased by farmers and subtracting from this the total farm land leased out by farmers.

We conducted another survey to gather similar information from users of the Happy Seeder machine. We obtained the list of users of Happy Seeder technology by contacting the manufacturer of the Happy Seeder machine and various government officials associated with its promotion. We collected data from 92 Happy Seeder users spread across the 7 districts of Punjab. Since the Happy Seeder is a new technology, most users experimented with it in a limited area while simultaneously practicing conventional tillage in the other areas.

We conducted the two surveys between January and April in 2010, with a follow-up via the telephone during June 2010 in order to obtain data on the yield of the wheat crop for all respondents.

### **3. Determinants of Rice Residue Burning**

#### **3.1 Descriptive Statistics**

Presently, four options are available to the farmers for the disposal of residue, namely, the complete burning of residue, the partial burning of residue, the in-corporation of residue into field and removal of the residue from the field. The combine-harvester leaves two types of residue into the field: loose residue and intact residue. Intact residue is the stalk of the rice plant that is left standing in the field after the combine-harvester has cut the top-most portion of the plant that carries the grain. Its height varies from 8 to 10 inches. Loose residue is the residue that is scattered by the combine-harvester after the harvesting and threshing of the rice crop. This part of the residue is hard to retrieve as it is unevenly distributed over the field. Complete burning involves burning the loose

<sup>3</sup> The decision to use the voter list as a sampling frame was taken after conducting a census of a village. The census revealed that the voter list is not grossly distorted. Hence we decided to use the voter list as a sampling frame.

and intact residue while partial burning involves burning loose residue only. Some farmers plow the loose and intact residue into the fields. They do this typically by using a tractor-drawn machine called a Rotavator. It involves a single pass of shallow intensive tillage that incorporates the anchored residue and pulverizes the soil. The incorporation of residue refers to this practice.

We found the mode of harvesting to strongly influence the choice of crop residue disposal. According to our sample, farmers burnt 1% of the residue of the rice plant that they manually harvested while they burnt 90% of the residue of the rice crop that was left by the combine-harvester (see Table 1). This is because manual harvesting allows for easy retrieval of the rice residue since the rice plant is cut at near ground level and collected into bundles for subsequent threshing. The recovery of stalks and stubble after harvesting by a combine-harvester, on the other hand, is more problematic since the cut residues (loose residue) is scattered all over the harvested fields.

This Table also shows that the type of rice variety grown by the farmer in turn drives the choice of the mode of harvesting. While there are two choices open to the farmers regarding the type of rice variety that they may grow, i.e., coarse varieties and fine grain (Basmati) varieties, we observed that farmers were more likely to harvest Basmati varieties manually. Two factors explain this observed difference, the most striking being the price differential between Basmati and coarse varieties. We discovered that the Food Corporation of India (FCI) procures rice and wheat from farmers at the minimum support price (MSP) announced by the Government of India. Farmers are free to sell any quantity of grain at this price. The fine grain (Basmati) varieties however do not fall under this scheme. Since the FCI announced the minimum support price in August 2009, farmers had to rely on the prices that had prevailed during the previous season.<sup>4</sup>

The Food Corporation of India (FCI) further classifies coarse varieties into grade A and common varieties, with the minimum support prices for grade A variety and common variety fixed at INR 980 per quintal (or USD 21 per quintal) and INR 950 per quintal (or USD 20 per quintal) respectively in 2009. The fine grain varieties are however priced within the range of INR 2000-3500 per quintal (or USD 43-75) depending on its quality. Since the use of the combine-harvester results in a loss of grain and given that the price of Basmati rice far exceeds the price of coarse rice, farmers prefer to opt for manual harvesting of Basmati varieties in order to minimize this loss. But, on the other hand, it is also much cheaper and quicker to use combine-harvesters than to employ labor. These time savings are dear to the farmers as there is only a short time period between rice harvesting (mid October-early December) and the sowing of wheat, which takes place between November and early December. Any delay in planting reduces the productivity of the wheat crop (Gupta et al., 2004). Consequently, combine-harvesters are popular with farmers for coarse varieties. Table 2 displays the mean rental rate of combine-harvesters and the wages for contract labor across the 3 districts in Punjab. Farmers in Ludhiana save about USD 112 per hectare by opting for a combine-harvester. The corresponding figures for Amritsar and Sangrur are USD 56 and 102 respectively.

### 3.2 Model of Farmers' Decision to Burn Rice Residue

As the above discussion implies, the mode of harvesting and the method of residue disposal are jointly determined by farmers. Since manual harvesting allows for maximum recovery of rice residue, farmers are less likely to burn this residue. On the other hand, since the combine harvester leaves much rice residue in the field, farmers have no choice but to burn it in order to ready the field for the wheat crop that follows almost immediately in the wake of the rice harvest.

Approximately, 90% of the respondents, when asked about the basis of variety choice, cited the price and yield of various varieties during the previous growing season as the key factors in arriving at this decision. For example, during the 2008-2009 period, the price of PUSA 1121 Basmati variety increased to INR 2000 (or USD 43) per quintal owing to its short supply in the market.<sup>5</sup> Consequently, farmers increased the area cultivated under this variety during the following season. PUSA 1121 variety, as a result, comprised 75% of the area under Basmati in my sample. Hence, I assume here that the decision of farmers on the type of rice variety that they sow is exogenously determined by agro-climatic conditions and the price and yield of rice varieties previously grown by the farmer.

<sup>4</sup> Rice is a kharif crop. There are 2 growing seasons in India i.e. kharif and rabi crop. Kharif crops are usually sown with the beginning of the rains in June-July, during the south-west monsoon season.

<sup>5</sup> Amritsar Procurement Centre (Mandi).

Taken as a whole, however, only 21% of the respondents in our sample cultivated Basmati varieties while 47% of the respondents cultivated coarse varieties. 32% of the respondents, on the other hand, grew both varieties. Figure 1 shows the district-wise distribution of gross cropped area under fine grain (Basmati) and coarse varieties for each of the three districts in our sample. In the sample, the area under Basmati and coarse varieties was 271 hectares and 869 hectares respectively but there was significant variation across districts. In Amritsar, for instance, 71% of the gross cropped area sown was Basmati while, in the case of Ludhiana, 52% of the gross cropped area sown was the coarse variety.

The reason for the predominance of fine grain varieties in Amritsar had to do with the agro-climatic conditions of this region that were conducive to growing Basmati varieties.<sup>6</sup> The Punjab governments decision to launch a Integrated Pest Management technology in the Basmati-growing areas of Amritsar, Tarn Taran and Gurdaspur districts at a cost of about INR 10 million (or USD 2,17,391) for the year 2009-2010 further reflects the concentration of Basmati varieties in this region.

These 3 districts in fact comprise the Basmati belt of Punjab.<sup>7</sup> Hence, we found the most precious Basmati varieties such as Super Basmati to be grown only in Amritsar although another variety called Muchal is sown in Sangrur. Therefore, although Basmati rice is produced in small quantities in other districts of Punjab, its characteristics quality-wise would not be the same as that of the fine indigenous varieties of Tarn Taran, Amritsar and Gurdaspur. Moreover, although shortage of labor compelled many farmers in our sample to resort to mechanical harvesting for Basmati varieties too, they always resorted to manual labor to harvest the expensive varieties of Basmati such as Super Basmati.

Thus, we treat the choice of harvesting method and choice of residue burning as two inter-dependent decisions that are not perfectly correlated but are jointly determined. We employ a recursive bivariate probit model with the method of harvesting and residue burning as the two dependent variables with the method of harvesting being the independent variable in the regression with residue burning as the dependent variable. The dependent variables are Burnt and Combine, where Burnt takes the value 1 if farmers burnt the residue (completely or partially) on a plot and 0 otherwise. Likewise, Combine equals 1 if farmers used a combine-harvester to harvest the rice crop on a plot and 0 otherwise. Thus, we assume that the decision to burn or not on the part of farmers is binary. We also assume that the method of residue disposal would influence the choice of the method of harvesting. However, this influence is not important enough given that there is no market for rice residue in the surveyed districts. Thus, in terms of profits, the residue disposal decision is not as important as the choice of the mode of harvest. Hence, we do not control for the method of residue disposal in the equation on the mode of harvesting.

The recursive bivariate probit model is a slight modification of the basic bivariate probit model with the method of harvesting appearing on the right-hand side of the equation of burning. The bivariate probit model considers two binary outcomes that are potentially related via correlation of errors that appear in the underlying latent variable models.

Let  $b=1$  denote burning of residue on a plot and  $b=0$  otherwise. Likewise  $c=1$  denotes usage of a combine machine on a plot and ' $c=0$ ' otherwise. Let  $b^*$  and  $c^*$  be unobserved, or latent variables, determined by

$$b^* = \chi'_{ibp} \beta_b + c'_p \gamma + \varepsilon_{ibp}$$

$$c^* = \chi'_{icp} \beta_c + \varepsilon_{icp}$$

$$E \left[ \varepsilon_{ibp} \mid \chi_{ibp}, \chi_{icp} \right] = E \left[ \varepsilon_{icp} \mid \chi_{ibp}, \chi_{icp} \right] = 0$$

$$Var \left[ \varepsilon_{ibp} \mid \chi_{ibp}, \chi_{icp} \right] = Var \left[ \varepsilon_{icp} \mid \chi_{ibp}, \chi_{icp} \right] = 1$$

$$Corr \left[ \varepsilon_{ibp}, \varepsilon_{icp} \mid \chi_{ibp}, \chi_{icp} \right] = \rho$$

<sup>6</sup> The Tribune, 2005 and conversations with farmers and agricultural scientists.

<sup>7</sup> Express India, 2008 and conversations with farmers and agricultural scientists.

where  $i$  and  $p$  are farmer and plot specific subscripts.  $\chi_{ibp}$  and  $\chi_{icp}$  is a vector of farmer and plot level attributes (for example, age, education, farm size, type of variety sown on a plot etc.) and  $\varepsilon_{ibp}$  and  $\varepsilon_{icp}$  are disturbance terms having zero means.

A single equation probit method is inefficient in that it ignores the possibility of correlation between the disturbances and in the underlying latent variable models (Greene, 1998). In this case, the disturbances have a bivariate normal distribution and therefore, we need to estimate these equations using a bivariate probit model (Greene, 1998).

The model collapses into two separate probit models for  $b$  and  $c$  if  $\rho = 0$  because when  $\rho$  is zero, the correlation between the disturbances equals zero. The most suitable technique of estimating a bivariate probit model is full information maximum likelihood. It turns out that despite the issue of endogeneity the terms that enter the likelihood of the recursive bivariate probit model are the same as those for the usual bivariate probit model (Greene, 1998).

Wilde (2000) has shown that identification by functional form is present in the recursive bivariate probit model in the absence of exclusion restrictions. However, the common practice is to impose restrictions to improve the identification of the model. In our model, we exclude the particular rice variety that farmers sow in order to identify the predicted value of  $c$  in the equation of burning. This is because the rice variety that farmers sow affects the method of residue disposal through its impact on the mode of harvesting. Once farmers make the choice regarding the mode of harvesting, the rice variety they sow plays no role in determining the method of residue disposal. So farmers never manually harvest coarse rice because the grain is not valuable enough to justify the extra cost. Conditional on combine harvesting, Table 1 therefore shows that there is little difference in residue disposal methods between Basmati and coarse varieties.

Incorporation of residue appears more common for Basmati varieties, but this is due to the prohibition on burning rice residue in Amritsar (see Appendix Table 1-3). The Deputy Commissioner (DC) of Amritsar enforced this ban for the first time in 2009 just prior to the rice-harvesting season in the district.<sup>8</sup> The punishment meted out to violators of the ban was the permanent disconnection of the power supply by the Punjab State Electricity Board.

Since the authorities banned burning rice residue just prior to the rice-harvesting season, the ban did not influence the type of rice variety farmers grew in Amritsar. Moreover, there is no reason to believe that had this prohibition been in place before the rice sowing period, it could have influenced the variety decision. In fact, in order to maximize profits, a majority of the farmers in Amritsar flouted the ban and resorted to burning rice residue (See Appendix Table 1). This shows that farmers did not take the ban seriously and that profit considerations were the major factor in determining the choice of the method of residue disposal.

The absence of reaper harvesting technology in rice underscores even more clearly the very limited use for the rice residue that remains on the field after harvesting the rice plant via a combine-harvester. On the other hand, this technology is in widespread use for the wheat crop. It harvests the wheat residue left in the field by the combine-harvester by chopping it so that farmers can use it as fodder for livestock. As mentioned earlier, wheat residues have a scarcity value and farmers trade the surplus. In contrast, as mentioned earlier, there is no market for rice residue in the surveyed districts. Thus, rice residue is not valuable enough to drive the harvesting decision.

### 3.3 Description of Variables

The variables that we have used in this study to explain the choice of the method of residue disposal and the mode of harvesting come out of the profit maximizing exercise of the farmer. Although we do not model profits explicitly, the preceding discussion seeks to identify which heterogeneous characteristics of farmers and their growing conditions influence their choice of harvesting and residue disposal. This discussion implies that the mode of harvesting, proxies of scale of operation and technical ability of the farmer, family size, age of the farmer and farm location explain the choice of the method of residue disposal. The raw data in fact suggests that small-scale farmers are more likely to remove the residue from their fields for the purpose of feeding livestock.

<sup>8</sup> The Tribune, 2009 and personal communication with the Deputy Commissioner.

Introducing a dummy variable that equals 1 if the farmer used a combine-harvester to harvest the rice crop on a plot and 0 otherwise captures the mode of harvesting. Farm size indicates the effect of scale of operation while family size is proxied by the number of family members equal to or above 15 years of age in the household per hectare of farm area sown to rice. Years of education of the farmer, viewership of a television program related to farming, contact with extension services, and whether farmer reads agricultural magazines are proxies for the technical ability of the farmer.<sup>9</sup> The dummy variable Amritsar represents location, which equals 1 if the plot is located in Amritsar and 0 otherwise.

The explanatory variables in the equation on the mode of harvesting are the rice variety farmers sow on a plot, ownership of livestock, farm size, family size, rental rate of a combine-harvester in the village, rental rate of contract labor in the village, age and education of the farmer, proxies of technical ability of the farmer and farm location. The rice variety that farmers sow has direct implications for the mode of harvesting (manual or combine). Small-scale farmers may be more inclined to use their own labor or employ labor to harvest Basmati varieties. Farmers who own livestock are more likely to harvest the crop manually. However, we allowed for this effect to vary with the rice variety that farmers sow since they prefer the residue of the Basmati variety for the purpose of feeding livestock. The location of the farm may influence the mode of harvesting even after controlling for the rice variety that farmers grow. This is because farmers in Amritsar plant high quality Basmati varieties that are more likely to be harvested manually.

The binary variable Coarse identifies the rice variety that farmers sow on a plot. It equals 1 if the variety of rice that farmers sow on a plot is coarse and 0 otherwise. The number of family members equal to or above 15 years of age in the household per hectare of farm area sown to rice is a proxy for family size. The number of livestock owned per hectare of farm area reflects ownership of livestock. Table 3 gives the descriptive statistics of the variables included in the analysis.

### 3.4 Discussion of Results

We estimated the recursive bivariate probit model using maximum likelihood. We corrected the standard errors for clustering at the farmer level. The estimated value of  $\rho$  was -0.16. The t ratio on this coefficient was -0.86 suggesting that the un-observables may be uncorrelated. The likelihood ratio test of the null hypothesis that  $\rho$  equals zero against the alternative that  $\rho$  does not equal zero reaffirms this result. The  $p$  value of  $\rho = 0$  is 0.39. Therefore, we cannot reject the null hypothesis at any conventional significance level, which indicates the validity of estimating the two equations separately. We however do not find this result surprising. The correlation coefficient measures the correlation between the outcomes after we have accounted for the influence of the explanatory variables. Thus, the value, -0.16, measures the effect of unobservables after we have already accounted for the influence of using a combine-harvester. However, as we will show later, the farmer's decision to use a combine-harvester to harvest the rice crop or not is the single most important determinant of whether a farmer will burn the residue on a plot. Hence, we estimated each equation using single equation probit methods.

### 3.5 Determinants of Mode of Harvesting

The most important factor affecting the farmers' choice of the mode of harvesting was the variety of rice that the farmer sowed (see Column 1, Table 4). We expected this result given the statistics in Table 2. On plots that were planted with coarse varieties, farmers were 63% more likely on average to use combine-harvesters. The number of livestock owned per hectare of farm area had some impact on the decision regarding the mode of harvesting. The average change in the predicted conditional probability where combine harvester equals 1 for a 1 unit increase in livestock per hectare of farm area differed between coarse and Basmati varieties by 7% points, with coarse rice growers having higher marginal effects on livestock on average. Farmers in Amritsar on average were significantly less likely to use a combine-harvester. This reflects farmer preference for manually harvesting high-quality Basmati varieties in this region. It is noteworthy that the variable Amritsar turned out to be statistically insignificant when we computed the marginal effects fixing the values of the variables Coarse and Amritsar at 1 and keeping all the other variables fixed at their mean values. This shows that plot location was of no consequence to the mode of harvesting

<sup>9</sup> If there were more than two active farmers in the same household, we used the information on the oldest farmer as a measure of the technical ability of that farming household.

for coarse varieties. The location variable Amritsar was statistically significant in the regression that excluded the variable Coarse. The average partial effect of the variable Amritsar increased to -0.39. This is because the variable Amritsar was picking up the effect of the variable Coarse. Since we can assume the location of a farmer to be exogenous at a given point in time, we can also assume the variety of rice that farmers sow to be exogenous. To see this more closely, we ran 2 separate regressions for each of the varieties using a linear probability model with village-fixed effects. As predicted, Amritsar was statistically significant in the regression for the Basmati variety and insignificant in the regression for the coarse variety. As in the probit model, the location dummy Amritsar was significant in the regression that excluded the variable Coarse.

The model predicted 91% of the plots on which farmers were using a combine-harvester correctly as well as 91% of the plots on which farmers were resorting to manual labor correctly, with an overall correct prediction rate of 91%. As a robustness check, we estimated this model using a linear probability framework with farm-fixed effects and village-fixed effects. We report the results in Columns 2-3 of Table 4. These results are consistent with the results in column 1.

We show the average marginal effects of the variables in the equation on method of residue disposal in column 1 of Table 5. The results on the method of residue disposal model indicated that the model successfully predicted 99% of all plots on which farmers burnt rice residue as well as 74% of all plots on which farmers did not burn residue, with an overall correct prediction rate of 90%.

By far, the usage of a combine-harvester exerted the most substantial effect, on average, on the probability that farmers will burn residue on a plot. Residue, on plots on which farmers harvested a rice crop using a combine-harvester, was 80% more likely to be burnt on average than residue on plots on which farmers harvested the rice plant using farm labor. Another factor influencing the decision to burn the residue was farm location. Plots located in Amritsar on average were 24% less likely to get burnt than plots situated in Ludhiana and Sangrur. Farm size, age of the farmer and availability of human capital appeared to have no influence on the decision to burn rice residue. These findings are consistent with the results obtained from the models that include farmer-fixed effects and village-fixed effects (see columns 2-3 of Table 5).

### **3.6 Examination of an Available Alternative to the Problem of Burning: The Happy Seeder Technology**

Our results imply that the most important determinant of the decision to burn rice residue is the use of a combine-harvester. While I find that the ban on the burning of residue imposed in Amritsar district has had, some impact on the frequency of burning, in the absence of any economically viable alternative to burning residue and adequate enforcement, it has not succeeded in eliminating the practice of residue burning. Furthermore, the use of a combine-harvester is not amenable to policy intervention because the advantages that combine-harvesters offer in terms of savings in money and time as well as reduced supervision of labor have made them immensely popular with today's farmers. At present, farmers use combine-harvesters mainly to harvest coarse varieties of rice in Punjab but, as the discussion in Section 4 shows, farmers who face a labor shortage may also resort to mechanical harvesting in the case of the Basmati varieties. Thus, labor scarcity is likely to increase the use of combine-harvesters among farmers.

It is possible to make a modification to the combine-harvester enabling the residue to be collected separately. This raises questions about the utilization of residue. Given that rice residue is of limited value to the farmers, whether as livestock feed or non-feed use, it remains to be seen whether uses can be found for rice residue outside the agricultural sector. The Government has introduced balers in the district of Amritsar. In addition, a sugar mill in the district is also using the baled residue to generate electricity in this district. However, the baling of residue may not be a viable mitigation strategy as the supply of baled residue may outweigh its demand. We have no way to substantiate this claim since there is no data available on the quantities of residue that various industries in Punjab demand and the quantities supplied.

Another viable alternative is incentives to develop machines that allow farmers to plant wheat into the loose residue. The Happy Seeder technology performs this function in the context of rice residue. Thus, an important

research question is whether the Happy Seeder technology is a viable alternative to open-field burning of rice residue. We address this question in the next section.

## **4. Development of the Happy Seeder Technology**

Engineers of CSIRO Griffith at Punjab Agricultural University developed the first prototype of the Happy Seeder in July 2001. The machine consisted of a standard Indian seed drill with inverted T-boots attached by a three-point linkage behind a forage harvester with a modified chute. Although preliminary tests of this technology with about 6 t/ha of anchored and loose rice residue were very encouraging, in some situations, the establishment of the wheat crop was poor. To deal with this problem, the engineers modified the Happy Seeder technology in 2004. They added a narrow strip tillage assembly in front of the sowing tynes to improve the contact of the seed with the soil. However, since there were persistent problems with this technology, the manufacturer modified it again in 2005 and 2006. At the time of our field survey, a manufacturer at Ramdass in the district of Gurdaspur in Punjab was manufacturing the Happy Seeder which had been first sold to a farmer in the district in 2007. However, to date, the Happy Seeder technology is undergoing modifications in its design and engineers continue to test it for its performance.

### **4.1 Comparison of Profits across Users and Non-users of Happy Seeder Technology**

#### **4.1.1 Comparison of Yields**

Since the Government of India determines the price of wheat, the use of the Happy Seeder can affect revenue from wheat production by affecting its yield. To determine the impact of Happy Seeder technology in comparison with conventional tillage with regard to yield per hectare of wheat sown, we estimated regressions that included farmer fixed effects. We used plot level data collected from the users of the Happy Seeder to conduct these regressions. As mentioned before, most farmers used Happy Seeder on a limited area while simultaneously using conventional tillage in other areas, thereby allowing us to control for farmer-fixed effects. The farmer-fixed effects eliminate any unobservable factors among farmers that might simultaneously affect yield and the performance of the Happy Seeder technology. Therefore, variations in yield were due to natural variations in the functioning of the Happy Seeder technology. We exploited this heterogeneity to estimate the effect of the new technology.

The explanatory variables include a set of plot-level and farmer-level characteristics (the size of the plot, soil type, quantity of fertilizers applied to a plot, age and education of the farmer and variables that measure the technical ability of the farmer such as whether the farmer watched a television program related to farming, etc.), and a binary variable named Happy Seeder that equals 1 if the farmers sow wheat on a plot using Happy Seeder technology and 0 otherwise.

It is not possible to control for the mode of irrigation as all farmers in the sample use a tube-well for irrigation. Since the government gives farmers electricity for free in Punjab, they are unable to provide information on the expenditure incurred on irrigation or the quantity of water used for irrigation. However, the farmer-fixed effect captures the effect of the quantity of water used for irrigation.

For the coefficient on the Happy Seeder variable to have a causal interpretation, the unobserved determinant of yield must remain uncorrelated with the Happy Seeder variable. Since farmer-fixed effects account for any potential confounding farmer-level characteristics, any correlation between yield and the treatment variable must be on account of unobserved plot-level characteristics. If the type of wheat variety that farmers sow on a plot affects yield and correlates with the Happy Seeder variable, the estimated coefficient on the Happy Seeder variable will be biased. Focus group discussions with farmers suggest that the type of wheat variety that farmers sow does not significantly affect the yield of wheat. We can expect the yields to differ at most by a magnitude of 1-2 quintals across varieties. However, to rule out the possibility of correlation between the type that farmers sow and the Happy Seeder variable, we control for the variety of wheat sown in the yield and the profit regressions. There may also be a plot-specific selection effect as farmers may choose to use the Happy Seeder on plots that they believe are more

suited for this technology. We control for the type of soil in a plot to account for this effect. Since the Happy Seeder is a new technology, farmers may not be aware of the plot characteristics that are appropriate for this technology. Hence, we can assume plot selection to be random.

Farmers can plant the seedlings of the wheat crop manually or by machines. The term for the seeding of a crop into unplowed fields is zero-tillage or no tillage. Besides the Happy Seeder, manufacturers have developed other machines that can grow zero-tillage wheat. Although zero-tillage depends on the use of a zero-tillage seed drill, farmers in Punjab use zero-tillage seed drills on conventionally tilled fields. Hence, we treat sowing of the wheat crop by zero-tillage seed drill as conventional tillage. Another tillage system involves the use of the Rotavator. The Rotavator is a recent introduction in the agricultural system of Punjab but I will treat it as conventional tillage as its usage involves the burning of residue and tillage. On the other hand, conventional tillage for wheat implies the burning of the rice residue followed by multiple passes of the tractor to accomplish plowing, harrowing, raking and seeding operations.

#### **4.1.2 Comparison of Costs**

The second question that we investigate in this section is whether the Happy Seeder technology was a low or high cost alternative to conventional tillage. For this purpose, we estimate regressions taking the cost incurred per hectare in establishing the wheat crop as the dependent variable. The explanatory variables in these regressions include the controls in the yield regressions, the output of the wheat crop in a plot, and the mean price per kg of fertilizer paid by the farmer. Nine respondents had purchased the Happy Seeder technology and consequently did not incur any expenditure to hire it. We assigned to them the average cost of using the Happy Seeder that prevailed in their district.<sup>10</sup>

A prerequisite for using the Happy Seeder is that the loose rice straw left by the combine-harvester should be spread uniformly on the field. Farmers mostly employed labor for spreading this residue although combine-harvesters with a spreader attached to them are available. In addition, farmers incurred expenditure on the purchase and application of weedicide and fertilizers.

We assigned farmers who had utilized their own labor for applying weedicide or for spreading the loose residue the prevailing wage rate in their village of applying the same.

The cost per hectare to prepare the field using the Happy Seeder comprised the cost of hiring the Happy Seeder, the diesel expenses incurred (if any) to operate it, the amount spent on spreading the residue and to apply weedicide, and the amount spent on purchasing fertilizers and weedicide.

As with the Happy Seeder technology, the total cost per hectare of establishing wheat with conventional tillage comprised the cost of hiring farm equipment and the diesel expenses incurred (if any) to operate it, and the amount spent on the purchase and application of weedicide and fertilizers. For the owners of farm machinery, we used the prevailing village rental to hire this equipment in order to impute the value of the service cost of farm equipment.

#### **4.1.3 Comparison of Profits**

We now estimate regressions taking profit per hectare from wheat production as the dependent variable in order to see whether the Happy Seeder technology is a profitable alternative to conventional tillage. The controls in these regressions are similar to the controls in the cost regression except that we do not control for the yield of the wheat crop. We give the descriptive statistics of the variables used in the analysis in Table 6.

### **4.2 Empirical Results**

Table 7 contains estimates of the effect of Happy Seeder technology on yield per hectare, cost per hectare and profit per hectare of wheat that farmers sow in a plot. In columns 1 to 3, we report the results of the regression model which has yield per hectare as the dependent variable. Column 1 shows the results of the random-effects

<sup>10</sup> If village level rates were not available, we used district level estimates to impute these rates.

model fitting them by generalized least squares. The coefficient on the Happy Seeder variable was negative (though small in magnitude) and insignificant. Thus, we do not find any impact on the yield of the wheat crop from using the Happy Seeder. The results in column 2 of Table 7 are estimates of the farmer-fixed effects model. We continued to find no effect on the yield of the wheat crop from operating the Happy Seeder. Column 3 presents the results of the pooled least squares estimation. The least squares results also imply that the Happy Seeder technology had no effect on the output of the wheat crop relative to conventional tillage.

Columns 4 to 6 display the results of the equation taking the cost incurred per hectare to prepare preparing the field of wheat as the dependent variable. The results from all the models (column 5) indicate that on average the Happy Seeder technology was a low-cost alternative compared to conventional tillage. The cost saving is highest in the fixed-effects model. Since the fixed-effects model controls for confounding factors at the farmer level, the result strongly indicates that among farmers who used the Happy Seeder technology, the plots that they cultivated using the Happy Seeder technology, on average, incurred a lower cost than those sowed using conventional tillage. This cost saving amounted to INR 1055 per hectare (USD 23).

In columns 7 to 9, we present the results of the model that estimates the effect of Happy Seeder technology on profitability. The results show that on average the Happy Seeder is not a more profitable alternative to conventional tillage, a finding that is consistent across specifications. These findings, however, are applicable to the users of the Happy Seeder technology. A question that is of relevance to policy is whether the Happy Seeder technology will work for the general population of farmers. In order to investigate whether the users of the Happy Seeder machine are comparable in farm characteristics to representative farmers, we compared the means of farm characteristics between the two samples in my study.

Table 8 shows the means of plot level characteristics between the users and non- users of the Happy Seeder. The Table also reports the test statistics for the difference in means across plots in the two samples (see columns 4, 5 and 6). The numbers in Table 8 indicate that the mean output of the wheat crop is similar across the three types of plots, i.e., those that were conventionally tilled and those that were cultivated using Happy Seeder technology. This is a noteworthy feature of the estimates. They imply that the mean yield of the wheat crop was not significantly different across plots that were conventionally tilled by users of the Happy Seeder and those by non-users of the Happy Seeder.

In Table 9, we report the statistics on farmer characteristics across the two samples. The users of the Happy Seeder were more educated and may be more technically able (as measured by indicators such as viewership of television programs on farming and subscription to agricultural magazines) than non-users of the Happy Seeder. We also found them to be better connected with the agricultural extension network. This is not surprising as the agricultural adoption literature highlights that a farmer's education and his connectivity with the extension network play a crucial role in his decision to adopt a new technology Rahm and Huffman, 1984 Dorfman, 1996 Nkamleu and Adesina, 2000.

We also performed the two-sample Welsch test to determine whether the difference in mean yield per hectare of the three most popular varieties of wheat in Punjab is statistically significant across the two samples. We found that none of the three differences in means were statistically significant. However, this may partly be due to the small sample size in the Happy Seeder category.

We have already established that for users of the Happy Seeder technology, the Happy Seeder is less expensive to use than conventional tillage. Thus, we now compare the field preparation costs incurred per hectare by users of the Happy Seeder with the corresponding expenses of non-users of the Happy Seeder. Figure 2 shows that the Happy Seeder users as a group have lower field preparation costs than users of conventional tillage. The median of the field preparation cost using the Happy Seeder is less than the first quartile of the distribution of field preparation costs borne by farmers that fully burnt their plots prior to sowing wheat. The notches surrounding the median determine the significance of differences between the values. If notches about two medians in particular do not overlap in the graph, the differences between the medians are statistically significant at the 95% confidence level (McGill et al., 1978).

This implies that the difference between the first box and the other boxes is significant. Users of the Happy Seeder saved around INR 1535 (or USD 33) per hectare in field preparation costs compared to non-users who completely burnt the residue. Incorporation of residue is the most expensive alternative. Hence it is not surprising that only 7.46% of the farmers in the sample incorporated the residue into the field.

Since the Happy Seeder technology is still in its infancy, the cost of hiring it varied considerably. The share of the cost of hiring a Happy Seeder machine in the total cost ranged from 0% to 98%. We re-estimated field preparation costs using the Happy Seeder technology assuming that the Happy Seeder machine is available for hiring for INR 1000 (or USD 21). This rate is the contract rate of a Roto broadcaster in Punjab that has similar power requirements and working width as the Happy Seeder technology (Singh et al., 2006). We expect the rental of the Happy Seeder machine to stabilize to this rate in the coming years. But the Happy Seeder machine continued to be a more viable option than the complete burning of rice residue among farmers using this technology.

In addition to the median, we also compared the means of field preparation costs for the 2 samples in our study. The difference in the means of field preparation costs of Happy Seeder users and those who had completely burnt their plots was INR. 2029 (or USD 44) per hectare. This difference was statistically significant at the 1% level with a ratio of -8.97. Thus, the cost saving per hectare of field preparation of wheat tends to be higher when the mean of the distribution of the field preparation costs are compared with the median.

## **5. Conclusions and Policy Implications**

We find that the use of coarse (as opposed to Basmati) varieties of rice increases the likelihood of harvest by combine-harvesters. In plots that were planted with coarse varieties, farmers, on average, were 63% more likely to use combine-harvesters. The use of the combine-harvester makes burning of residue almost certain. Rice residue left behind by the combine-harvester was 80% more likely to be burnt than residue left after harvesting the rice crop using manual labor. The ban on burning residue imposed in Amritsar district had some impact on the frequency of burning. The number of livestock per hectare of farm area, farm size, and variables that measure the availability of human capital did not seem to have an impact on the probability of burning rice residue.

We conclude that rice residue is largely burnt because it is of limited value to the farmers both as livestock feed and non-feed use. Since the machinery for planting wheat into loose rice residue was hitherto unavailable, farmers burnt the rice residue. The Happy Seeder technology overcomes this problem by planting wheat into the loose residue. Our results imply that the Happy Seeder technology is a viable alternative to open-field burning of rice residue in Punjab. Operators of this technology saved about INR.1000-1060 (or USD 23) on average in field preparation costs compared to plots that were conventionally tilled. We also found that the Happy Seeder technology was a cheaper alternative to conventional tillage for non-users of this technology. Specifically, the median of the field preparation cost using the Happy Seeder was INR 6353 (or USD 138) per hectare whereas the median of field preparation costs incurred by farmers who fully burnt their plots prior to sowing wheat was INR 7888 (USD 171) per hectare.

The difference between the two medians of INR 1535 (or USD 33) was statistically significant. This cost saving was higher when we compared the means of these two distributions. Increasing the availability of combine-harvesters that have a spreader attached to them can further lower the costs of using the Happy Seeder technology. This enables farmers to evenly spread the loose residue. In fact, Singh et al., suggest that the yield of the wheat crop may also be negatively impacted if the loose residue is unevenly spread on the field (2006). This latter feature merits the development of more such harvesters.

However, this decrease in cost may or may not be significant enough to motivate farmers to switch to the Happy Seeder technology. Therefore, policymakers must take measures to demonstrate to the farmers that they enjoy substantial savings in time because the Happy Seeder can be brought into the field immediately after the rice harvest enabling farmers to sow wheat while the rice straw is still too green to burn. The Happy Seeder technology is beneficial given the externalities generated by residue burning. Thus, with the current available information on this technology, policy-makers and other interested parties should play a more proactive role in promoting its further use through extension services and the possible use of subsidies. Subsequent experience with this technology will inform about its long term impact on soil fertility and yield.

According to the findings of our study, the Happy Seeder therefore has no strong advantage or disadvantage from the point of view of the private profitability of the farmer. Our study clearly demonstrates that, left to itself, the Happy Seeder can be expected to spread only slowly. Therefore, policy-makers and other interested parties should play a more proactive role in promoting its use through extension and subsidies in order to reduce residue burning, the costs of which are mostly external to the farmer as a private individual but borne by the entirety of the society and of the planet. However, there needs to be further research in order to assess the long term impact of the Happy Seeder technology on soil fertility and yield when promoting its use as an alternative technology to conventional tillage among farmers.

## **Acknowledgements**

This research was supported by a grant from the South Asian Network for Development and Environmental Economics (SANDEE), Nepal. I am grateful to E. Somanathan, Jean Marie Baland, Mani Nepal, Abhiroop Mukhopadhyay, Kensuke Kubo, Jeffrey Vincent and Priya Shyamsundar for their suggestions on this research. I thank Harjit Singh and Shyam Kumar for an excellent implementation of the surveys. Last but not least, I am deeply indebted to the farmers of Punjab, who are too numerous to mention individually, but without whose cooperation this study would not have been possible. Errors, if any, are my own.

District	Mean Rental Rate of Combine INR per Hectare (USD in Parenthesis)	Mean Rental Rate of Contract Labor INR per Hectare (USD in Parenthesis)	Ratio of Mean Rate Labor to Mean Rental Combine
Amritsar	2304 (49)	4993 (105)	2
Ludhiana	1621 (35)	6871 (147)	4
Sangrur	1619 (35)	6378 (136)	4

Notes: The exchange rate used through out the analysis is as on September 7, 2008 i.e. USD 1= INR 46.82

**Table 3: Description of the Variables Used in the Analysis**

Variables	Description	Unit of Measurement	Variables	
			Mean	S.D.
Burnt	Indexes the method of residue disposal on a plot. 1 = residue is burnt , 0 = otherwise	Percent of Plots	0.64	0.48
Combine	Whether or not farmer used a Combine to harvest rice on a plot. 1 = Combine machine is used, 0 = otherwise	Number of Plots	0.74	0.44
Coarse	Type of variety of rice sown by the farmer on a plot. 1 = coarse, 0 = Basmati	Number of Plots	0.64	0.48
Farm Size	Size of a farm unit	Hectares	5.03	5.51
Livestock per hectare of farm area		Number	2.46	1.96
Watch	Whether or not farmer watched a television program on farming. 1 = Watches, 0 = Does not watch	Number of Farmers	0.56	0.50
Contact with Extension	Whether or not an extension agent visited the farmer in the year preceding the survey 1 = Yes, 0 = No	Number of Farmers	0.24	0.43
Reads Magazines	Does the farmer read agricultural magazines? 1 = Yes, 0 = No	Number of Farmers	0.20	0.40
Age of the Farmer		Number	51.73	14.21
Education of the Farmer		Number	8.16	4.1
Number of Persons Equal to or Above 15 years of Age in the Household per hectare of Farm Area Sown to Rice		Number	2.71	2.91
Rental Rate of Combine-Harvester in Village		Rupees per Hectare	1889.55 (\$16.34)	400.05
Rental Rate of Contract Labor in Village		Rupees per Hectare	5882.717 (\$50.84)	1460.73
Amritsar	Dummy Variable that equals 1 if a plot is located in Amritsar, 0 otherwise	Number of Plots	0.32	0.47
Number of Plots	Number of plots in the sample	Number	604	
Number of Farmers	Number of farmers in the sample	Number	268	

**Table 4: Marginal Effect of the Variables on Choice of Harvesting in Punjab 2010**

Variables	Probit Method (Average Marginal Effect)	Linear Probability Model	
		Farmer Fixed Effect (Marginal Effect)	Village Fixed Effect (Marginal Effect)
Coarse	.6275*** (17.98)	.5036*** (8.38)	.5123*** (7.42)

R Squared	-	0.70	0.50
Pseudo R Squared	0.60		

Notes: Dependent variable is Burnt. Burnt = 1 if the farmer burnt residue on a plot and 0 otherwise. Figures in parenthesis are t-ratios. For probit regression the standard errors are clustered at the farmer level and robust standard errors are reported for the farmer and village fixed effects.

\*\*\*indicates significance at the 1% level, \*\*indicates significance at the 5% level, \*indicates significance at the 10% level.

**Table 6: Description of the Variables Used in the Analysis**

Variables	Description	Unit	Means (Standard Deviation in Parenthesis)		
			Plots sown with Conventional Tillage	Plots sown using Happy Seeder	Entire Sample
Yield per hectare	Quantity of wheat produced per hectare on a plot	Quintals	43.81 (4.317)	43.31 (6.193)	43.57 (5.286)
Cost per hectare	Per hectare expenditure incurred on preparing the field of wheat	INR	7288.54 (2657.56)	6225.3 (1235.1)	6780.32 2161.80)
Profit per hectare	Per hectare profit earned from wheat production	INR	40024.4 (5318.05)	40548.27 (6644.97)	40274.81 (5975.51)
Happy Seeder	Whether or not farmer used Happy Seeder to sow wheat on a plot 1 = happy Seeder is used, 0 = otherwise	No. of plots	-	-	(0.48) (0.50)
Plot Size	Size of a plot	He ctares	6.039 (5.760)	5.342 (5.630)	5.706 (5.691)
Fertilizer	Quantity of fertilizers applied per hectare of wheat	Kg	473.09 (87.88)	461.00 (97.09)	467.28 (92.30)
Price of Fertilizer	Mean price of fertilizers	Price per kg	-	-	7.14 (12.75)
Age	Age of farmer	No. of farmers	48.92 (13.08)	49.83 (12.45)	49.35 (12.75)
Education	Years of Education of Farmer	No. of farmers	10.30 (2.67)	10.05 (3.27)	10.18 (2.96)
Watch	Whether or not farmer watched a television programme on farming 1 = Watches, 0 = Does not watch	No. of farmers	0.57 (0.50)	0.59 (0.50)	0.58 (0.50)
Contact with Extension	Whether or not an extension agent visited the farmer in the year preceding the survey 1 = Yes, 0 = No	No. of farmers	0.69 (0.47)	0.65 (0.48)	0.67 (0.47)
Reads Magazines	Does the farmer read agricultural magazines? 1 = Yes, 0 = No	No. of farmers	0.48 (0.50)	0.49 (0.50)	0.48 (0.50)
Variety 1	If the variety sown on a plot is of type 1 1 = Yes, 0 = No	No. of plots	0.28 (0.45)	0.22 (0.42)	0.25 (0.44)
Variety 2	If the variety sown on a plot is of type 2 1= Yes, 0 = No	No. of plots	2.20 (0.41)	0.29 (0.46)	0.25 (0.43)
Variety 3	If the variety sown on a plot is of type 3 1 = Yes, 0 = No	No. of plots	0.25 (0.44)	0.30 (0.46)	0.28 (0.45)
Variety 4	If the variety sown on a plot is of type 4 1 = Yes, 0 = No	No. of plots	0.07 (0.26)	0.05 (0.22)	0.06 (0.24)
Variety 5	If the variety sown on a plot is of type 5 1 = Yes, 0 = No	No. of plots	0.19 (0.40)	0.13 (0.34)	0.16 (0.37)

Variables	Description	Unit	Means (Standard Deviation in Parenthesis)		
			Plots Sown with Conventional Tillage	Plots Sown using Happy Seeder	Entire Sample
Soil Type 1	If the soil type on a plot is of type 1 1=Yes, 0=No	No. of Plots	0.10 (0.30)	0.07 (0.25)	0.08 (0.27)
Soil Type 2	If the soil type on a plot is of type 2 1=Yes, 0=No	No. of Plots	0.04 (0.19)	0.11 (0.31)	0.07 (0.25)
Soil Type 3	If the soil type on a plot is of type 3 1=Yes, 0=No	No. of Plots	0.40 (0.49)	0.43 (0.50)	0.42 (0.49)
Soil Type 4	If the soil type on a plot is of type 4 1=Yes, 0=No	No. of Plots	0.19 (0.40)	0.12 (0.33)	0.16 (0.37)
Soil Type 5	If the soil type on a plot is of type 5 1=Yes, 0=No	No. of Plots	0.05 (0.22)	0.04 (0.20)	0.04 (0.21)
Soil Type 6	If the soil type on a plot is of type 6 1=Yes, 0=No	No. of Plots	0.22 (0.42)	0.24 (0.43)	0.23 (0.42)
Number of Plots	Number of plots in the sample	No.	83	76	159
Percentage of plots	Percent of plots in the sample	No.	52	48	100
Number of Farmers	Number of farmers in the sample	No.	66	66	66

Notes: The Happy Seeder technology was made available to 22 respondents free of cost whereas 1 farmer could not be contacted for obtaining the data on the yield of the wheat crop. 3 farmers burnt the rice stubble prior to using Happy Seeder. This reduced the sample size to 66 farmers for the profitability analysis. We do not report the descriptive statistics for soil type and type of variety of wheat sown for the sake of brevity.

Number of Farmers	88	88	88	66	66	66	66	66	66

Notes: The dependent variable in column 1 to 3 is yield per hectare of wheat in a plot. The dependent variable in column 3 to 6 is cost incurred per hectare (in INR) on field preparation of wheat in a plot. The dependent variable in column 7 to 9 is per hectare profit earned (in INR) from wheat production in a plot. Figures in parenthesis are t-ratios. For OLS regressions the standard errors are clustered at the farmer level and robust standard errors are reported for the farmer fixed and random effects. The coefficients on the soil type and variety of wheat sown are not reported for the sake of brevity.

\*\*\* indicates significance at the 1% level, \*\* indicates significance at the 5% level, \* indicates significance at the 10% level.

**Table 8: Descriptive Statistics and Mean Differences Between the plots of Users and Non-Users of Happy Seeder**

	Means, Sample of Plots Cultivated using Conventional Tillage by Non-users of Happy Seeder	Means, Sample of Plots Cultivated using Conventional Tillage by Users of Happy Zeeder	Means, Sample of Plots Cultivated using Happy Seeder by Users of Happy Seeder	T-test, Differences between Means in Column 1 and Column 2	T-test, Differences between Means in Column 1 and Column 3	T-test Differences between Means in Column 2 and Column 3
Characteristics	(1)	(2)	(3)	(4)	(5)	(6)
Yield Per Hectare	43.84 (0.269)	43.67 (0.468)	43.65 (0.736)	0.169 (0.566)	0.194 (0.662)	0.025 (0.844)
